TRACE METALS IN CLAMS (*MACOMA BALTHICA*) AND SEDIMENTS
AT THE PALO ALTO MUDFLAT IN SOUTH SAN FRANCISCO BAY:
MAY 1991 THROUGH MAY 1992

By Samuel N. Luoma, Daniel J. Cain, Cynthia Brown and Michelle Hornberger

ABSTRACT

This report presents trace element concentrations analyzed on samples of sediment and clams (*Macoma balthica*) collected from a mudflat one kilometer south of the discharge of the Palo Alto sewage treatment works. Samples were collected on ten occasions between May, 1991 and May 1992, at near monthly intervals. A previous report compared concentrations of silver and copper from this mudflat with values observed at other stations in San Francisco Bay in earlier studies (Luoma and others, 1991). Changes in concentrations of these metals were also compared from near monthly collections between 1977 and 1991. In this report we update this data set, emphasizing the recent data, changes observed between 1986 and 1992, and the seasonality of copper and silver concentrations in 1991 and 1992.

INTRODUCTION

Sediments and benthic organisms are commonly employed to determine spatial distributions and temporal trends of trace metal contamination in estuarine waters. Sediments bind metals strongly, removing them from solution. The result is that sediments may progressively accumulate the metals released to an environment, and concentrations of metals may be indicative of anthropogenic releases to an environment, integrated over time.

Metals in sediments are also indicative of the exposure of animals in contact with benthic and suspended particulate materials. However, it is not well known what proportion of sediment-bound metal is passed on to living organisms. In order to better estimate bioavailable metal exposures, the tissues of the organisms themselves may be analyzed for trace metals. Most species concentrate metals to levels higher than occur in solution, but different species concentrate metals to different degrees. Nevertheless, analysis of one species has been successfully employed to indicate trace element exposures to the food web of the organism. For example, Ag, Cu and Se contamination originally observed in clams (*Macoma balthica*) at a Palo Alto mudflat was later also found in diving ducks, snails, and mussels from that area.

Purpose

The purpose of this study is to present trace metal concentrations observed in sediments and clams at a mudflat in south San Francisco Bay. The station, termed here the Palo Alto mudflat, is located one kilometer south of the intertidal discharge point of the Palo Alto publically-owned treatment works (POTW). The data reported here are from samples collected on ten dates

between May 15, 1991 and May 6, 1992. These data and data collected from earlier studies will be used to approach three questions:

1. What are concentrations of Ag, Cd, Cr, Cu, Ni, Pb, V and Zn in clams that reside in sediments at the Palo Alto mudflat and in sediments from that site?
2. How do concentrations of metals in clams and sediments at Palo Alto in 1991-92 compare with concentrations observed in 1990-91?
3. What are the trends in copper and silver concentrations at the Palo Alto mudflat between 1986 and 1992? Specifically, are concentrations of these elements in 1991-92 changing compared to concentrations observed at this locality in recent years?

Study Site

The data from this study were collected from site 3 (fig. 1) of the transect conducted by Thomson and others (1984) along the Palo Alto shoreline. Although the highest concentrations of copper and silver were observed in clams and sediments adjacent to the Palo Alto POTW discharge (site 5 in fig. 1) in that study, contamination also was observed at site 3. The influence of the POTW on metal concentrations at site 3 also was demonstrated by Cain and Luoma (1990). They showed a similarity in temporal trends at site 3 between metal discharge from the POTW and concentrations in clam tissues. Results from both studies thus indicated that environmental metal concentrations at site 3 were indicative of POTW metal discharges.

Another important conclusion from Cain and Luoma (1990) and Luoma and others (1985) was that concentrations of metals fluctuated on nearly monthly time scales in the Palo Alto mudflat environment. Thus frequent sampling within a year (at near monthly intervals) was necessary to characterize contamination for that year. The data presented in this report follow those procedures.

SAMPLING PROCEDURES

All samples were collected from the exposed mudflat at low tide. Sediment samples were scraped from the surface oxidized layers (1 -2 cm) of mudflat. Thus, these samples represent recently deposited sediments, or sediments affected by recent chemical reactions. Sediments were immediately returned to the laboratory in Menlo Park after collection. There they were sieved through 100 micrometer polyethylene mesh with ocean water adjusted to ambient salinity to remove large grains that might bias interpretation of concentrations. The mesh size was chosen by the largest grains typically found in the digestive tract of the indicator organism *Macoma balthica*. Previous studies have shown little difference between sieved and unsieved sediments in the silt-clay type sediment that predominates at this station, but this procedure reduces the likelihood that changes are the result of sampling sediments of different character. The sediments that passed through the sieve were allowed to settle overnight. The water was then decanted, leaving a slurry of sediment of particle size less than 100 micrometers. Subsamples of wet sediment were collected from the slurry using a pipette while swirling. Replicate subsamples were further washed to remove salts then dried at 60° celsius to obtain a representative dry weight. Subsamples from different collections ranged from 86 to 153 milligrams in weight. Replicates agreed within 10 percent of mean sample weight. Replicate subsamples were digested for "total" metal analysis by refluxing in 10 milliliters of concentrated

nitric acid until the digest was clear. Samples were then evaporated to dryness and reconstituted in dilute (5 percent) hydrochloric acid for analysis. The hydrochloric acid matrix was specifically chosen because it mobilizes Ag into solution through creation of Ag-chloro complexes. Another set of replicate samples was subjected to a partial weak acid extraction, as a crude chemical estimate of bioavailable metal. These subsamples were extracted for 2 hours with 10 ml of five percent hydrochloric acid at room temperature (Luoma and Bryan, 1981). The extract was then pressure filtered through a 0.45 micrometer membrane filter.

The deposit feeding clam *Macoma balthica* was collected simultaneously with the sediment samples. More than 40 individuals were collected at each sampling, and the range of sizes (shell length) was maximized by intensive field sampling. Animals were returned to the laboratory and held for 48 hours in ocean water diluted to the ambient salinity at the time of sampling. This was done to depurate undigested material from their digestive tracts. After depuration the individual clams were separated into size classes (determined by differences of one millimeter shell length). Each size class was composited for a single sample, and soft tissues were removed. Samples for each date thus were composed of eight to twelve replicate composites, with each composite consisting of animals of a similar shell length. Animal samples were dried, weighed and refluxed in concentrated nitric acid until the digest was clear. Digests were then dried and reconstituted in dilute (5 percent) hydrochloric acid for analysis.

All metal analyses were conducted by Inductively Coupled Argon Plasma Emission Spectroscopy (ICAPES). Selected tissue samples were also analyzed by Atomic Absorption Spectroscopy to compare with the results of ICAPES analysis. Data from the two types of analyses were not significantly different ($p>0.10$). Analyses of NBS reference materials (bovine liver, oyster tissue) were also routinely conducted to assure adequate recovery and accurate analyses. Values were all within the acceptable range reported by NITS. Peaks were censored from the data if they did not exceed 10 standard deviations of the background noise (limit of quantification), with the exception of silver in sediments. Silver peaks were censored if they did not exceed 3 standard deviations (limit of detection). Most detectable silver concentrations from sediments fell between the limit of detection and limit of quantification.

RESULTS OF ANALYSES

Although our procedures do not allow a rigorous quantitative estimate of population size, it was noticeable from late 1991 through May 1992 that the abundance of *M. balthica* had increased dramatically from earlier years. We have observed in the past that clam populations at the Palo Alto mudflat were noticeably reduced during years of very low freshwater input to San Francisco Bay (1976 through 1977; 1985 through early 1991). The recovery of abundances in 1992 was an exception. In our 1990 to 1991 sampling, 5 person hours were typically required to collect forty to sixty animals. This number could easily be collected in one to two person hours in 1992. Our on-going work will include analyses of clam "condition" to assess if the physiological status of this population is indeed changing.

Appendix 1 lists all sediment analyses, and Appendix 2 lists all metal analyses of clam tissues conducted from the May 1991 to May 1992 samples. Analytical data and detection limits also are given for each sample to aid in verification of peaks. Statistical data indicates size influences on tissue concentrations, and content calculations are reported with summary statistics in Appendix 2.

Table 1 lists monthly variability in mean silver and copper concentrations observed in clams and sediments from the study site between May 1991 and May 1992. Figures 2 and 3 compare the seasonality observed in 1991 to 1992 with seasonality observed in 1990 to 1991. Tables 2 and 3 compare the 1991 - 92 data to long-term temporal trends observed in the copper and silver concentrations of clams since 1977. These data are annual mean concentrations calculated from the 7 to 11 samples collected between May of one year and April of the next. Figures 4, 5 and 6 illustrate the trends in these data in recent years, so as to better put perspective on changes in 1991 to 1992. From these figures and tables the data collected in 1991-92 can be compared with earlier levels of contamination at this station.

APPENDIX 1. Metal concentrations in sediments collected at the Palo Alto mudflat. Each monthly collection is reported on a separate page. Concentrations observed in the reconstituted samples or extracts (in micrograms per milliliter or ug/ml) are reported at the top of each page, along with the sediment weight and dilution factor. The latter are employed to determine concentrations in sediments (reported as microgram per gram dry sediment or ug/g). Replicate subsamples were analyzed from each collection. Mean and standard deviation for the replicate samples are reported for the total and hydrochloric acid extracts.

APPENDIX 2. Metal concentrations in the clam *Macoma balthica* collected at the Palo Alto Mudflat. Each monthly collection is reported on two pages. The first page contains summary statistics:

Mean concentrations in microgram per gram dry tissue weight (ug/g).

STD is the standard deviation of the mean.

SEM is the standard error of the mean.

CV percent is the coefficient of variation.

$r_{wt \times []}$ is the correlation coefficient for the concentration versus weight correlation for each element.

X 100mg is the concentration interpolated from the above regression for a 100 mg animal.

$r_{l \times []}$ is the correlation coefficient for the concentration versus shell length regression.

X 20 mm and X 25 mm are concentrations interpolated from the regression for 20mm and 25 mm animals.

Content (a measure of metal bioaccumulation that is independent of mass) is also shown for 20 and 25 mm animals, as is the weight determined for animals of 15 mm and 20 mm shell length.

The second page for each month shows each analysis of each composite sample, the number of animals composited in each, concentration as calculated from sample dry weight and the dilution factor and the metal content for each sample.
